## 1 Introduction

We are given a set of points  $y_1, \dots, y_n$  and imagine they are realisations of a random distribution  $p(y)$ . We would like to know how  $p(y)$  looks like. A commonly used method is the following: suppose that there is a set of possible random distribution functions  $P(y)$  in which  $p(y)$  exists. Then we assume that there exists a set  $\Theta$  and a function  $\Theta \rightarrow P(y)$  which we call a *parametrisation*. Usually,  $\Theta$  is a simpler set to study than  $P(y)$ . Then, statistics is concerned with using the observed  $y_1, \dots, y_n$  to draw a  $\theta \in \Theta$  such that  $\theta \mapsto p(y)$  is as “close” as possible to the “true”  $p(y)$ .

Unlike in the usual statistical context, we view the parameter  $\theta$  as being itself random with some distribution  $p(\theta)$ . We define the joint probability of  $y$  and  $\theta$  as being a function  $p(y, \theta)$  such that

$$p(\theta) = \int p(y, \theta) dy$$
$$\text{and } p(y) = \int p(y, \theta) d\theta$$

Then we define the conditional distribution “of  $y$  given  $\theta$ ” as

$$p(y|\theta) = \frac{p(y, \theta)}{p(\theta)}.$$

Using this property twice we obtain Bayes’ theorem which allows us to “invert” and obtain the distribution of  $\theta$  given the observed  $y$ . Since we only observe a finite number of  $y$  this is only an approximate distribution, we will talk about uncertainty later on.

$$p(\theta|y) = \frac{p(y, \theta)}{p(y)} = \frac{p(\theta)p(y|\theta)}{p(y)}.$$

In practice, the factor  $p(y)$  is nothing to worry about since we can obtain it by integrating away  $\theta$  in the following way,  $p(y) = \int p(y|\theta)p(\theta)d\theta$ .

## 2 Bayesian hierarchical models

Suppose we observe values  $y_{ij} \sim P(\theta_j)$  where  $j = 1, \dots, J$  and  $i = 1, \dots, n_j$ . So, in other words we have a certain number of observations, each belonging to some group, and the values within each group are i.i.d with parameter  $\theta_j$ . We will discuss here two methods to analyze such data that will motivate the use of hierarchical models.

It might at first seem appealing to ignore the differences between groups, this means setting all the  $\theta_j$  to be equal to each other and now we can perform usual maximum likelihood estimation. Using this method may cause a problem if there is a group with only a few outlying observations. If this happens, the outlying group will have an estimate that is far from its observations.

Then another idea might be to treat each group as a separate estimation, as though they have nothing to do with each other. In some cases, this is justified, but it poses another problem for our outlying group with only a few observations. In this case, since that group only has a few observations we will get estimates with a large variance.

Finally, the idea of hierarchical models is to see the first two methods as two extremes: “the  $\theta_j$  are the same” and “the  $\theta_j$  are the same”. Instead we will imagine that the  $\theta_j$  are themselves distributed  $\theta_j \stackrel{\text{i.i.d.}}{\sim} Q(\phi)$ . For some fixed parameter  $\phi$ .

## 3 Graphical models

We observe a set of points  $y_1, \dots, y_n$ . In particular the covariance for these points  $\text{cov}(y_i, y_j)$  for  $i, j = 1, \dots, n$  is unknown and not necessarily zero. We would like to obtain estimates for  $p(y_i | y_1, \dots, y_n)$ .
